
Maximum-entropy and representative samples of neuronal activity: a dilemma

Abstract

1 The present work shows that the maximum-entropy method can be applied to a
2 sample of neuronal recordings along two different routes: (1) apply to the sample;
3 or (2) apply to a larger, unsampled neuronal population from which the sample
4 is drawn, and then marginalize to the sample. These two routes give inequivalent
5 results. The second route can be further generalized to the case where the size of the
6 larger population is unknown. Which route should be chosen? Some arguments are
7 presented in favour of the second. This work also presents and discusses probability
8 formulae that relate states of knowledge about a population and its samples, and
9 that may be useful for sampling problems in neuroscience.

10 1 Introduction: maximum-entropy and recordings of neuronal activity

11 Suppose that we have recorded the firing activity of a hundred neurons, sampled from a particular
12 brain area. What are we to do with such data? Gerstein, Perkel, Dayhoff [1] posed this question very
13 tersely (our emphasis):

14 The principal conceptual problems are (1) *defining cooperativity or functional*
15 *grouping* among neurons and (2) *formulating quantitative criteria* for recognizing
16 and characterizing such cooperativity.

17 These questions have a long history, of course; see for instance the 1966 review by Moore et al.
18 [2]. The neuroscientific literature has offered several mathematical definitions of ‘cooperativity’ or
19 ‘functional grouping’ and criteria to quantify it.

20 One such quantitative criterion relies on the maximum-entropy or relative-maximum-entropy method
21 [3–7]. This criterion has been used in neuroscience at least since the 1990s, applied to data recorded
22 from brain areas as diverse as retina and motor cortex [8–24], and it has been subjected to mathematical
23 and conceptual scrutiny [25–31].

24 ‘Cooperativity’ can be quantified and characterized with maximum-entropy methods in several ways.
25 The simplest way roughly proceeds along the following steps. Consider the recorded activity of a
26 sample of n neurons.

- 27 1. The activity of each neuron, a continuous signal, is divided into T time bins and binarized in
28 intensity, and thus transformed into a sequence of digits ‘0’s (inactive) and ‘1’s [cf. 32; 33].
29 Let the variable $s_i(t) \in \{0, 1\}$ denote the activity of the i th sampled neuron at time bin t .
30 Collectively denote the n activities with $s(t) := (s_1(t), \dots, s_n(t))$. The population-averaged
31 activity at that bin is $\bar{s}(t) := \sum_i s_i(t)/n$. If we count the number of distinct pairs of
32 active neurons at that bin we combinatorially find $\binom{n\bar{s}(t)}{2} \equiv n\bar{s}(t)[n\bar{s}(t) - 1]/2$. There

33 can be at most $\binom{n}{2}$ simultaneously active pairs, so the population-averaged pair activity is
 34 $\bar{s}\bar{s}(t) := \binom{n}{2}^{-1} \binom{n\bar{s}(t)}{2}$. With some combinatorics we see that the population-averaged activity
 35 of m -tuples of neurons is

$$\underbrace{\bar{s} \cdots \bar{s}}_{m \text{ terms}}(t) = \binom{n}{m}^{-1} \binom{n\bar{s}(t)}{m}. \quad (1)$$

36 For brevity let us agree to simply call ‘activity’ the average \bar{s} , ‘pair-activity’ the average $\bar{s}\bar{s}$,
 37 and so on.

38 2. Construct a sequence of relative-maximum-entropy distributions for the activity \bar{s} , using
 39 this sequence of constraints:

- 40 • the time average of the activity: $\hat{\bar{s}} := \sum_t \bar{s}(t)/T$;
- 41 • the time averages of the activity and of the pair-activity $\hat{\bar{s}\bar{s}} := \sum_t \bar{s}\bar{s}(t)/T$;
- 42 • ...
- 43 • the time averages of the activity, of the pair-activity, and so on, up to the k -activity.

44 Call the resulting distributions $p_1(\bar{s}), p_2(\bar{s}), \dots, p_k(\bar{s})$. The time-bin dependence is now
 45 absent because these distributions can be interpreted as referring to any one of the time bins
 46 t , or to a new time bin (in the future or in the past) containing new data.

47 We also have the empirical frequency distribution of the total activity, $f(\bar{s})$, counted from
 48 the time bins.

49 3. Now compare the distributions above with one another and with the frequency distribution,
 50 using some probability-space distance like the relative entropy or discrimination information
 51 [34; 4; 35; 5]. If we find, say, that such distance is very high between p_1 and f , very low
 52 between p_2 and f , and is more or less the same between all p_m and f for $m \geq 2$, then we
 53 can say that there is a ‘pairwise cooperativity’, and that any higher-order cooperativity is
 54 just a reflection or consequence of the pairwise one. The reason is that the information from
 55 higher-order simultaneous activities did not lead to appreciable changes in the distribution
 56 obtained from pair activities.

57 The protocol above needs to be made precise by specifying various parameters, such as the width of
 58 the time bins or the probability distance used.

59 We hurry to say that the description just given is just *one* way to quantify and characterize cooperativity
 60 and functional grouping, not *the only* way. It can surely be criticized from many points of view. Yet,
 61 it is quantitative and bears a more precise meaning than an undefined, vague notion of ‘cooperativity’.
 62 Two persons who apply this procedure to the same data will obtain the same numbers. Different
 63 protocols can be based on the maximum-entropy method, for instance protocols that take into account
 64 the activities or pair activities of specific neurons rather than population averages, or even protocols
 65 that take into account time dependence.

66 The purpose of the present work is not to assess the merits of maximum-entropy methods with respect
 67 to other methods. Its main purpose is to show that there is a problem in the way the maximum-entropy
 68 method itself, as sketched above, is applied to the activity of the recorded neurons. We believe that
 69 this problem is at the root of some quirks about this method that were pointed out in the literature
 70 [27]. This problems extends also to more complex versions of the method, possibly except version
 71 that use ‘hidden’ neurons [36–39]. The problem is that the recorded neurons are a *sample* from a
 72 larger, unrecorded population, but the maximum-entropy method as applied above is treating them as
 73 isolated from the rest of the brain. Hence, the results it provides cannot rightfully be extrapolated. We
 74 will give a mathematical proof of this. Let us first analyse this issue in more detail.

75 Suppose that the neurons were recorded with electrodes covering an area of some square millimetres
 76 [cf. 40]. This recording is a sample of the activity of the neuronal population under the recording
 77 device; which can amount to tens of thousands of neurons [41]. We could even consider the recorded
 78 neurons as a sample of a brain area more extended than the recording device.

79 The characterization of the cooperativity of the recorded sample would have little meaning if we did
 80 not expect its results to generalize to a larger, unrecorded population – at the very least that under the
 81 recording device. In other words, we expect that the conclusions drawn with the maximum-entropy
 82 methods about the sampled neurons should somehow extrapolate to unrecorded neurons in some

larger area, from which the recorded neurons were sampled. In statistical terms we are assuming that the recorded neurons are a *representative sample* of some larger neuronal population. Probability theory tells us how to make inferences from a sample to the larger population from which it is sampled (see references below).

We can apply the maximum-entropy method to the sample, as described in the above protocol, to generate probability distributions for the activity of the sample. But, given that our sample is representative of a larger population, we can also apply the maximum-entropy method to the larger (unrecorded) population. The constraints are the same: the time averages of the sampled data, since they constitute representative data about the larger population as well. The method thus yields a probability distribution for the larger population, and the distribution for the sample is obtained by marginalization. The problem is that *the distributions obtained from these two applications differ*. Which choice is most meaningful?

In this work we develop the second way of applying the maximum-entropy method, at the level of the larger population, and show that its results differ from the application at the sample level. We also consider the case where the size of the larger population is unknown.

To apply the maximum-entropy method to the larger, unsampled population, it is necessary to use probability relations relevant to sampling [42; 43 parts I, VI; 44 ch. 8; 45 ch. 3]. The relations we present are well-known in survey sampling and in the pedagogic problem of drawing from an urn without replacement, yet they are somewhat hard to find explicitly written in the neuroscientific literature. We present and discuss them in the next section. A minor purpose of this paper is to make these relations more widely known, because they can be useful independently of maximum-entropy methods.

The notation and terminology in the present work follow ISO and ANSI standards [46–50] but for the use of the comma ‘,’ to denote logical conjunction. Probability notation follows Jaynes [45]. By ‘probability’ we mean a degree of belief which ‘would be agreed by all rational men if there were any rational men’ [51].

2 Probability relations between population and sample

We have already introduced the notation for the sample neurons. We introduce an analogous notation for the ν neurons constituting the larger population, but using the corresponding Greek letters: $\sigma_i(t)$ is the activity of the i th neuron at time bin t , $\bar{\sigma}(t) := \sum_i \sigma_i(t)/\nu$ is the activity at that bin averaged over the larger population, and so on.

The probability relations between sample and larger population are valid at every time bin. As we mentioned above, the maximum-entropy distribution refers to any time bin or to a new bin. For these reasons we will now omit the time-bin argument ‘(t)’ from our expressions.

Probabilities refer to statements about the quantities we observe. We use the standard notation:

$$\begin{aligned} \Sigma_i = \sigma_i & \text{ stands for ‘the activity of the } i\text{th neuron is } \sigma_i\text{’,} \\ \bar{\Sigma} = \bar{\sigma} & \text{ stands for ‘the (population-averaged) activity of the neurons is } \bar{\sigma}\text{’,} \\ S_i = s_i & \text{ stands for ‘the activity of the } i\text{th sample neuron is } s_i\text{’,} \end{aligned} \quad (2)$$

and similarly for other quantities.

If K denotes our state of knowledge – the evidence and assumptions backing our probability assignments – our uncertainty about the full activity of the larger population is expressed by the joint probability distribution

$$P(\Sigma_1 = \sigma_1, \Sigma_2 = \sigma_2, \dots, \Sigma_\nu = \sigma_\nu | K) \quad \text{or} \quad P(\Sigma = \sigma | K), \quad \sigma \in \{0, 1\}^\nu. \quad (3)$$

Our uncertainty about the state of the sample is likewise expressed by

$$P(S_1 = s_1, S_2 = s_2, \dots, S_n = s_n | K) \quad \text{or} \quad P(S = s | K), \quad s \in \{0, 1\}^n. \quad (4)$$

The theory of statistical sampling is covered in many excellent texts, for example Ghosh & Meeden [42] or Freedman, Pisani, & Purves [43 parts I, VI]; summaries can be found in Gelman et al. [44 ch. 8] and Jaynes [45 ch. 3].

126 We need to make an initial probability assignment for the state of the full population before any
 127 experimental observations are made. This initial assignment will be modified by our experimental
 128 observations, and these can involve just a sample of the population. Our state of knowledge and
 129 initial probability assignment should reflect that samples are somehow representative of the whole
 130 population.

131 In this state of knowledge, denoted I , we know that the neurons in the population are biologically or
 132 functionally similar, for example in morphology or the kind of input or output they receive or give.
 133 But we are completely ignorant about the physical details of the individual neurons. Our ignorance
 134 is therefore symmetric under permutations of neuron identities. This ignorance is represented by a
 135 probability distribution that is symmetric under permutations of neuron identities; such a distribution
 136 is usually called *finitely exchangeable* [52; 42 ch. 1]. We stress that this probability assignment is just
 137 an expression of the symmetry of our *ignorance* about the state of the population, not an expression
 138 of some biologic or physical symmetry or identity of the neurons.

139 The *representation theorem for finite exchangeability* states that, in the state of knowledge I , the
 140 symmetric distribution for the full activity is completely determined by the distribution for its
 141 population-average:

$$P(\mathbf{Z} = \boldsymbol{\sigma} | I) \equiv \sum_{\bar{\boldsymbol{\sigma}}} P(\mathbf{Z} = \boldsymbol{\sigma} | \bar{\mathbf{Z}} = \bar{\boldsymbol{\sigma}}, I) P(\bar{\mathbf{Z}} = \bar{\boldsymbol{\sigma}} | I) = \left(\frac{\nu}{\nu \bar{\boldsymbol{\sigma}}} \right)^{-1} P(\bar{\mathbf{Z}} = \bar{\boldsymbol{\sigma}} | I). \quad (5)$$

142 The equivalence on the left is just an application of the law of total probability; the equality on the
 143 right is the statement of the theorem. This result is intuitive: owing to symmetry, we must assign
 144 equal probabilities to all $\binom{\nu}{\nu \bar{\boldsymbol{\sigma}}}$ activity vectors with $\nu \bar{\boldsymbol{\sigma}}$ active neurons; the probability of each activity
 145 vector is therefore given by that of the average activity divided by the number of possible vector
 146 values. Proof of this theorem and generalizations to non-binary and continuum cases are given by
 147 de Finetti [53], Kendall [54], Ericson [55], Diaconis & Freedman [56; 57], Heath & Sudderth [58].

148 Our uncertainties about the full population and the sample are connected via the conditional probab-
 149 ility

$$P(\bar{\mathbf{S}} = \bar{s} | \bar{\mathbf{Z}} = \bar{\boldsymbol{\sigma}}, I) = \binom{n}{n\bar{s}} \left(\frac{\nu - n}{\nu \bar{\boldsymbol{\sigma}} - n\bar{s}} \right) \left(\frac{\nu}{\nu \bar{\boldsymbol{\sigma}}} \right)^{-1} =: \Pi(\bar{s} | \bar{\boldsymbol{\sigma}}), \quad (6)$$

150 which is a hypergeometric distribution, typical of ‘drawing without replacement’ problems. The
 151 combinatorial proof of this expression is in fact the same as for this class of problems [45 ch. 3; 59
 152 § 4.8.3; 60 § II.6].

153 Using the conditional probability above we obtain the probability for the activity of the sample:

$$P(\bar{\mathbf{S}} = \bar{s} | I) = \sum_{\bar{\boldsymbol{\sigma}}} P(\bar{\mathbf{S}} = \bar{s} | \bar{\mathbf{Z}} = \bar{\boldsymbol{\sigma}}, I) P(\bar{\mathbf{Z}} = \bar{\boldsymbol{\sigma}} | I) = \sum_{\bar{\boldsymbol{\sigma}}} \Pi(\bar{s} | \bar{\boldsymbol{\sigma}}) P(\bar{\mathbf{Z}} = \bar{\boldsymbol{\sigma}} | I). \quad (7)$$

154 It should be proved that the probability distribution for the full activity of the sample is also symmetric
 155 and completely determined by the distribution of its population-averaged activity:

$$P(\mathbf{S} = \mathbf{s} | I) = \left(\frac{n}{n\bar{s}} \right)^{-1} P(\bar{\mathbf{S}} = \bar{s} | I). \quad (8)$$

156 This is intuitively clear: our initial symmetric ignorance should also apply to the sample. The
 157 distribution for the sample (7) indeed satisfies the same representation theorem (5) as the distribution
 158 for the full population.

159 The conditional probability $P(\bar{\mathbf{S}} = \bar{s} | \bar{\mathbf{Z}} = \bar{\boldsymbol{\sigma}}, I) \equiv \Pi(\bar{s} | \bar{\boldsymbol{\sigma}})$, besides relating the distributions for the
 160 population and sample activities via marginalization, also allows us to express the expectation value
 161 of any function of the sample activity, $g(\bar{s})$, in terms of the distribution for the full population, as
 162 follows:

$$E(g | I) \equiv \sum_{\bar{s}} g(\bar{s}) P(\bar{\mathbf{S}} = \bar{s} | I) = \sum_{\bar{s}} g(\bar{s}) \sum_{\bar{\boldsymbol{\sigma}}} \Pi(\bar{s} | \bar{\boldsymbol{\sigma}}) P(\bar{\mathbf{Z}} = \bar{\boldsymbol{\sigma}} | I) = \sum_{\bar{\boldsymbol{\sigma}}} \left[\sum_{\bar{s}} g(\bar{s}) \Pi(\bar{s} | \bar{\boldsymbol{\sigma}}) \right] P(\bar{\mathbf{Z}} = \bar{\boldsymbol{\sigma}} | I), \quad (9)$$

163 where the second step uses eq. (7). The last expression shows that the expectation of the function
 164 $g(\bar{s})$ is equal to the expectation of the function $g^*(\bar{\sigma}) := \sum_{\bar{s}} g(\bar{s}) \Pi(\bar{s} | \bar{\sigma})$.

165 The final expression in eq. (9) is important for our maximum-entropy application: the requirement
 166 that the function g , defined for the sample, have a value c obtained from observed data, *translates*
 167 *into a linear constraint for the distribution of the full population*:

$$c = E(g | I) \equiv \sum_{\bar{\sigma}} \left[\sum_{\bar{s}} g(\bar{s}) \Pi(\bar{s} | \bar{\sigma}) \right] P(\bar{\Sigma} = \bar{\sigma} | I). \quad (10)$$

168 In particular, when the function g is the m -activity of the sample, $g(\bar{s}) = \overline{s \dots s} \equiv \binom{n\bar{s}}{m} / \binom{n}{m}$, we find

$$E(\overbrace{s \dots s}^{m \text{ factors}} | I) \equiv \sum_{\bar{s}} \binom{n}{m}^{-1} \binom{n\bar{s}}{m} P(\bar{S} = \bar{s} | I) = \binom{\nu}{m}^{-1} \sum_{\bar{\sigma}} \binom{\nu\bar{\sigma}}{m} P(\bar{\Sigma} = \bar{\sigma} | I) \equiv E(\overbrace{\sigma \dots \sigma}^{m \text{ factors}} | I), \quad (11)$$

169 that is, *the expected values of the m -activities of the sample and of the full population are equal*. The
 170 proof of the middle equality uses the expression for the m th factorial moment of the hypergeometric
 171 distribution and can be found in Potts [61]. Similar relations can be found for the raw moments $E(\bar{s}^m)$
 172 and $E(\bar{\sigma}^m)$, which can be written in terms of the product expectations using eq. (1).

173 Thus, in a maximum-entropy application, when we require the expectation of the m -activity of a
 174 sample to have a particular value, we are also requiring the expectation of the m -activity of the full
 175 population to have the same value.

176 These expectation equalities between sample and full population should not be surprising: we
 177 intuitively *expect* that the proportion of coloured balls sampled from an urn should be roughly
 178 equal to the proportion of coloured ball contained in the urn. The formulae in the present section
 179 formalize and mathematically express our intuition. The hypergeometric distribution $\Pi(\bar{s} | \bar{\sigma})$ plays
 180 an important role in this formalization. A look at its plot, fig. 1, reveals that it is a sort of ‘fuzzy
 181 identity transformation’, or fuzzy Kronecker delta, between the $\bar{\sigma}$ -space $\{0, \dots, \nu\}$ and \bar{s} -space
 182 $\{0, \dots, n\}$. From eq. (8) we thus have that

$$P(\bar{S} = a | I) \approx P(\bar{\Sigma} = a | I), \quad E[g(\bar{s}) | I] \approx E[g(\bar{\sigma}) | I], \quad (12)$$

183 where g is any smooth function defined on $[0, 1]$. These approximate equalities express the intuitive
 184 fact that *our uncertainty about the sample is representative of our uncertainty about the population*

Figure 1: Log-density plot of the hypergeometric distribution $\Pi(\bar{s} | \bar{\sigma}) := \binom{n}{n\bar{s}} \binom{\nu-n}{\nu\bar{\sigma}-n\bar{s}} \binom{\nu}{\nu\bar{\sigma}}^{-1}$ for $\nu = 5000, n = 200$. (Band artifacts may appear in the colourbar depending on your PDF viewer.)

185 *and about other samples*, and vice versa. When $n = \nu$, $\Pi(\bar{s} | \bar{\sigma})$ becomes the identity matrix and the
 186 approximate equalities above become exact – of course, since we have sampled the full population.

187 But the approximate equalities above may miss important features of the two probability distributions.
 188 In the next section we will in fact emphasize their differences. If the distribution for the population
 189 average $\bar{\sigma}$ is bimodal, for example, the bimodality can be lost in the distribution for the sample
 190 average \bar{s} , owing to the coarsening effect of $\Pi(\bar{s} | \bar{\sigma})$.

191 3 Maximum-entropy: sample level vs full-population level

192 In the previous section we have seen that observations about a sample can be used as constraints on
 193 the distribution for the activity of the full population. Let us use such constraints with the maximum-
 194 entropy method. Suppose that we want to constrain m functions of the sample activity, vectorially
 195 written $\mathbf{g} := (g_1, \dots, g_m)$, to m values $\mathbf{c} := (c_1, \dots, c_m)$. These functions are typically k -activities
 196 $\bar{s} \dots \bar{s}$, and the values are typically the time averages of the observed sample, as discussed in § 1:
 197 $\mathbf{c} = \sum_t \mathbf{g}[\bar{s}(t)]/T$.

198 Let us apply the relative-maximum-entropy method [6; 7] directly to sampled neurons; denote this
 199 approach by I_s . Then we apply the method to the full population of neurons, most of which are
 200 unsampled; denote this approach by I_p .

201 Applied directly to the sampled neurons, the method yields the distribution

$$P(\bar{\mathbf{S}} = \bar{\mathbf{s}} | I_s) = \frac{1}{z(\mathbf{l})} \binom{n}{n\bar{\mathbf{s}}} \exp[\mathbf{l}^\top \mathbf{g}(\bar{\mathbf{s}})] \quad (13)$$

202 where $z(\mathbf{l})$ is a normalization constant. The binomial in front of the exponential appears because we
 203 must account for the multiplicity by which the population-average activity \bar{s} can be realized: $\bar{s} = 0$
 204 can be realized in only one way (all neurons inactive), $\bar{s} = 1/n$ can be realized in n ways (one active
 205 neuron out of n), and so on. This term is analogous to the ‘density of states’ in front of the Boltzmann
 206 factor in statistical mechanics [62 ch. 16]. The m Lagrange multipliers $\mathbf{l} := (l_1, \dots, l_m)$ must satisfy
 207 the m constraint equations

$$c_k = E(g_k | I_s) \equiv \frac{1}{z(\mathbf{l})} \sum_{\bar{\mathbf{s}}} g_k(\bar{\mathbf{s}}) \binom{n}{n\bar{\mathbf{s}}} \exp[\mathbf{l}^\top \mathbf{g}(\bar{\mathbf{s}})], \quad k = 1, \dots, m. \quad (14)$$

208 Applied to the full population, using the constraint expression (10) derived in the previous section,
 209 the method yields the distribution for the full-population activity

$$P(\bar{\mathbf{S}} = \bar{\sigma} | I_p) = \frac{1}{\zeta(\boldsymbol{\lambda})} \binom{\nu}{\nu\bar{\sigma}} \exp\left[\boldsymbol{\lambda}^\top \sum_{\bar{\mathbf{s}}} \mathbf{g}(\bar{\mathbf{s}}) \Pi(\bar{\mathbf{s}} | \bar{\sigma})\right]. \quad (15)$$

210 The m Lagrange multipliers $\boldsymbol{\lambda} := (\lambda_1, \dots, \lambda_m)$ must satisfy the m constraint equations

$$c_k = E(g_k | I_p) \equiv \frac{1}{\zeta(\boldsymbol{\lambda})} \sum_{\bar{\mathbf{s}}} \sum_{\bar{\sigma}} g_k(\bar{\mathbf{s}}) \Pi(\bar{\mathbf{s}} | \bar{\sigma}) \binom{\nu}{\nu\bar{\sigma}} \exp\left[\boldsymbol{\lambda}^\top \sum_{\bar{\mathbf{s}}} \mathbf{g}(\bar{\mathbf{s}}) \Pi(\bar{\mathbf{s}} | \bar{\sigma})\right], \quad k = 1, \dots, m. \quad (16)$$

211 We obtain the distribution for the sample activity by marginalization, using eq. (8):

$$P(\bar{\mathbf{S}} = \bar{\mathbf{s}} | I_p) = \frac{1}{\zeta(\boldsymbol{\lambda})} \sum_{\bar{\sigma}} \Pi(\bar{\mathbf{s}} | \bar{\sigma}) \binom{\nu}{\nu\bar{\sigma}} \exp\left[\boldsymbol{\lambda}^\top \sum_{\bar{\mathbf{s}}} \mathbf{g}(\bar{\mathbf{s}}) \Pi(\bar{\mathbf{s}} | \bar{\sigma})\right]. \quad (17)$$

212 The distributions for the sample activity, eqs (17) and (13), obtained with the two approaches I_s
 213 and I_p , are different. From the discussion in the previous section we expect them to be vaguely
 214 similar; yet they cannot be exactly equal, because their equality would require the $2m$ quantities
 215 $\boldsymbol{\lambda}$ and \mathbf{l} to satisfy the constraint equations (16) and (14), and in addition also the n equations
 216 $P(\bar{\mathbf{S}} = \bar{\mathbf{s}} | I_p) = P(\bar{\mathbf{S}} = \bar{\mathbf{s}} | I_s)$, $\bar{s} = 1/n, \dots, 1$ (one equation is taken care of by the normalization of the
 217 distributions). We would have a set of $2m + n$ equations in $2m$ unknowns.

218 Hence, *the applications of maximum-entropy at the sample level and at the full-population level are*
 219 *inequivalent*. They lead to numerically different distributions for the sample activity \mathbf{s} .

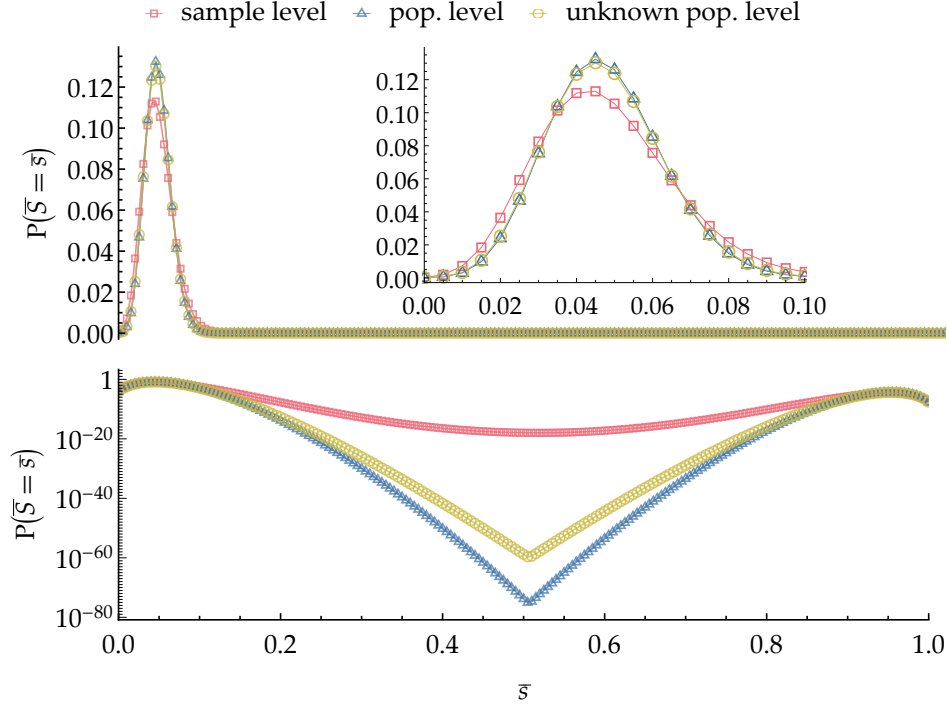

Figure 2: Linear and log-plots of $P(\bar{S} = \bar{s})$ for a sample of $n = 200$ and constraints as in eq. (18), constructed by: **red squares**: maximum-entropy at the sample level, eq. (13); **blue triangles**: maximum-entropy at the population level, eq. (17) with $\nu = 10\,000$, followed by sample marginalization; **yellow circles**: maximum-entropy at the population level with unknown population size, eq. (19), according to the distribution (20) for the population.

The distribution obtained at the sample level will show different features from the one obtained at the population level, like displaced or additional modes or particular tail behaviour. We show an example of this discrepancy in fig. 2, for $\nu = 10\,000$, $n = 200$, and the two constraints

$$E(\bar{s}) = 0.0478, \quad E(\bar{s}\bar{s}) = 0.00257, \quad (18)$$

which come from the actual recording of circa 200 neurons from macaque motor cortex [31]. The distribution obtained at the population level (blue triangles) has a higher and displaced mode and a quite different behaviour for activities around 0.5 than the distribution obtained at the sample level (red squares).

In our discussion we have so far assumed the size ν of the larger population to be known. This is rarely the case, however. We usually are uncertain about ν and can only guess its order of magnitude. In such a state of knowledge I_u our ignorance about the possible value of ν is expressed by a probability distribution $P(N = \nu | I_u) = h(\nu)$, and the marginal distribution for the sample activity (17) is modified, by the law of total probability, to

$$P(\bar{S} = \bar{s} | I_u) = \sum_{\nu} P(\bar{S} = \bar{s} | N = \nu, I_u) P(N = \nu | I_u) = \sum_{\nu} \left\{ \frac{1}{\zeta(\lambda_{\nu})} \sum_{\bar{\sigma}} \Pi_{\nu}(\bar{s} | \bar{\sigma}) \binom{\nu}{\bar{\sigma}} \exp\left[\lambda_{\nu}^T \sum_{\bar{s}} \bar{s} \Pi_{\nu}(\bar{s} | \bar{\sigma})\right] \right\} h(\nu), \quad (19)$$

where the Lagrange multipliers λ_{ν} and the summation range for $\bar{\sigma}$ depend on ν .

As a proof of concept, fig. 2 also shows such a distribution (yellow circles) for the same constraints as above, and a probability distribution for ν inspired by Jeffreys [63 § 4.8]:

$$h(\nu) \propto 1/\nu, \quad \nu \in \{1\,000, 2\,000, \dots, 10\,000\}. \quad (20)$$

4 Discussion

The purpose of the present work was to point out and show, in a simple set-up, that the maximum-entropy method can be applied to recorded neuronal data in a way that accounts for the larger population from which the data are sampled, eqs (15)–(17). This application leads to results that differ from the standard application which only considers the sample in isolation, eqs (13)–(14). We gave a numerical example of this difference. We have also shown how to extend the new application when the size of the larger population is unknown, eq. (19).

The latter formula, in particular, shows that the standard way of applying maximum-entropy implicitly assumes that *no* larger population exists beyond the recorded sample of neurons. One could in fact object to the application at the population level, and say that the traditional way of applying maximum-entropy, eq. (13), yields different results because it does not make assumptions about the size ν of a possibly existing larger population. Such a state of uncertainty, however, is correctly formalized according to the laws of probability by introducing a probability distribution for ν , and is expressed by eq. (19). This expression cannot generally be equal to (13) unless the distribution for ν gives unit probability to $\nu = n$; that is, unless the sample *is* the full population, and no larger population exists.

The standard maximum-entropy approach therefore assumes that the recorded neurons constitute a special subnetwork, isolated from the larger network of neurons in which it is embedded, and which was also present under the recording device. This assumption is unrealistic. The maximum-entropy approach at the population level does not make such assumption and is therefore preferable. It may reveal features in a data set that were unnoticed by the standard maximum-entropy approach.

The difference in the resulting distributions between the applications at the sample and at the population levels appears in the use of Boltzmann machines with hidden units [64], although by a different conceptual route. It also appears in statistical mechanics: if a system is statistically described by a maximum-entropy Gibbs state, its subsystems cannot be described by a Gibbs state [65]. A somewhat similar situation also appears in the statistical description of the final state of a non-equilibrium process starting and ending in two equilibrium states: we can describe our knowledge about the final state either by (1) a Gibbs distribution, calculated from the final equilibrium macrovariables, or (2) by the distribution obtained from the Liouville evolution of the Gibbs distribution assigned to the initial state. The two distributions differ (even though the final *physical* state is obviously exactly the same [66 § 4]), and the second allows us to make sharper predictions about the final physical state thanks to our knowledge of its preceding dynamics. In this example, though, both distributions are usually extremely sharp and practically lead to the same predictions. In neuroscientific applications, the difference in predictions of the sample vs full-population applications can instead be very relevant.

The idea of the new application leads in fact to more questions. For instance:

- Do the standard and new applications lead to different or contrasting conclusions about ‘cooperativity’, when applied to real data sets?
- How to extend the new application to the ‘inhomogeneous’ case [12; 13; 27], in which expectations for individual neurons or groups of neurons are constrained?
- What is the mathematical relation between the new application and maximum-entropy models with hidden neurons [36–39]?

Owing to space limitations we must leave a thorough investigation of these questions to future work.

Finally, we would like to point out the usefulness and importance of the probability formulae that relate our states of knowledge about a population and its samples, presented in § 2. This kind of formulae is essential in neuroscience, where we try to understand properties of extended brain regions from partial observations. The formulae presented here reflect a simple, symmetric state of ignorance. More work is needed [cf. 67] to extend these formulae to account for finer knowledge of the cerebral cortex and its network properties.

Acknowledgments

To be added after review.
